wolfgang.konen@th-koeln.de

February 2017

Abstract

This technical report introduces GBG, the general board game playing and learning framework. It is a tutorial that describes the set of interfaces, abstract and non-abstract classes which help to standardize and implement those parts of board game playing and learning that otherwise would be tedious and repetitive parts in coding. GBG is suitable for arbitrary 1-player, 2-player and n-player board games. It provides a set of agents (AI's) which can be applied to any such game. This document describes the main classes and design principles in GBG. GBG is written in Java.

1 Introduction

1.1 Motivation

General board game (GBG) playing and learning is a fascinating area in the intersection of machine learning, artificial intelligence and game playing. It is about how computers can learn to play games not by being programmed but by gathering experience and learning by themselves (self-play). The learning algorithms are often called AI agents or just „AI“'s (AI = artificial intelligence). There is a great variety of learning algorithms around, e.g. reinforcement learning algorithms like TD(λ), Monte Carlo tree search (MCTS), different neural network algorithms, Minimax, ... to name only a few.

Even if we restrict ourselves to board games, as we do in this paper (and do not consider other games like video games), there is a plethora of possible board games where an agent might be active in. The term „General“ in GBG refers to the fact that we want to have in the end agents or AIs which perform well on a large variety of games. There are quite different games: 1-person games (like Solitaire, 2048, ...), 2-person games (like Tic-Tac-Toe, Othello, Chess, ...), many-person games (like Settlers of Catan, Poker, ...). The game environment may be deterministic or it may contain some elements of chance (like rolling the dices, ...).

A common problem in GBG is the fact, that each time a new game is tackled, the AI developer has to undergo the frustrating and tedious procedure to write adaptations of this game for all agent algorithms. Often he/she has to reprogram many aspects of the agent logic, only because the game logic is slightly different to previous games. Or a new algorithm or AI is invented and in order to use this AI in different games, the developer has to program instantiations of this AI for each game.

Wouldn't it be nice if we had a framework consisting of classes and interfaces which abstracts the common processes in GBG playing and learning? If someone programs a new game, he/she has just to follow certain interfaces described in the GBG framework, and then can easily use and test on that game all AIs in the GBG library.

Likewise, if an AI developer introduces a new learning algorithm which can learn to play games, she has only to follow the interface for agents laid down in the GBG framework to test this new agent on all games of GBG. Once the interface is implemented she can directly train her agent, inspect its move decisions in each game, test it against other agents, run competitions, enter game leagues, log games and so on.

The rest of this document introduces the class concept of GBG. GBG is

written in Java. Sec. 2 gives an overview of the relevant classes and Sec. 3 discusses them in detail. Sec. 4 discusses some use cases for the GBG class framework. The appendix lists the methods of the important classes and interfaces.

1.2 Related work

Hoyle presented in Epstein [2001] is an early general board game playing program. It learned to play 18 diverse board games, where its strategic principles are general and not game specific. The software implementation of Hoyle is not further described in Epstein [2001].

Méhat and Cazenave [2010] show a study of single player games in the GGP (General Game Playing) context where they use variants of Monte Carlo Tree Search. The program is based on Ary, which is written in C with a Prolog interface engine. The program was tested on 22 single player games.

TODO: Michulke and Thielscher [2009]

TODO: Mańdziuk and Świechowski [2012] (with example Connect4, Othello)

There is so far no general board game playing framework in Java which allows AI-based agents to be compared with human play.

2 Class and Interface Overview

Interface StateObservation is the main interface a game developer has to implement once he/she wants to introduce a new game. A class derived from StateObservation observes a game state, it can infer from it the available actions, knows when the game is over, can advance a state into a new legal state given one of the available actions. If a random ingredient from the game environment is necessary for the next action (of the next player), the advance function will add it.

The second interface a game developer has to implement is the interface GameBoard, which realizes the board GUI and the interaction with the board. If one or more humans play in the game, they enter their moves via GameBoard.

The interface an AI developer has to implement is the interface PlayAgent It represents an „AI“ or agent capable of playing games. If necessary, it can be trained by self-play. Once trained, it has methods for deciding about the best next action in a StateObservation game state and getting the agent's estimate of the score or value of a certain game state.

The heart of GBG are the abstract classes Arena and ArenaTrain. In the Arena all agents meet: They can be loaded from disk, they play a certain game, there can be competitions. In ArenaTrain, which is a class derived from Arena, there are additional options to parametrize, train, inspect, evaluate and save agents.

The helper classes Feature and Evaluator support the abstraction in the classes Arena and ArenaTrain.

3 Classes in Detail

3.1 Interface StateObservation

Interface **StateObservation** observes the current state of the game, it has utility functions for

- returning the available actions (`getAvailableActions()`),
- advancing the state of the game with a specific action (`advance()`),
- copying the current state
- signaling end, score and winner of the game

If a game has random elements (like rolling the dices in a dice game or placing a new tile in 2048), `advance()` is additionally responsible for invoking such random actions and reporting the results back in the new state. Examples:

- For a dice-rolling game: the game state is the board & the dice number.
- For 2048: the game state is just the board (with the random tile added).

Implementing classes: StateObserverTTT, StateObserver2048, ...

As an example, StateObserverTTT is a state observer for the game Tic-TacToe: It has constructors with game-specific parameters (`int [][] table, int Player`). It has access functions `getTable()` and `getPlayer()`. The latter returns the Player who has to move in the current state.

3.2 Interface PlayAgent and class AgentBase

Interface **PlayAgent** has all the functionality that an AI (= game playing agent) needs. The most important methods are:

- `getNextAction(sob,...)`: given the current game state `sob`, return the best next action.
- `double getScore(sob)`: the score (agent's estimate of final reward) for the current game state `sob`.
- `trainAgent(sob,...)`: train agent for one episode[1] starting from state `sob`.

Some more methods, e.g. setters and getters, have their defaults implemented in class **AgentBase**.[2] It might be useful to design a new agent class with the signature `... extends AgentBase implements PlayAgent`.

There is an additional method `double estimateGameValue(sob)` which has the default implementation `getScore(sob)` in **AgentBase**. This method is called when a training game is stopped prematurely because the maximum number of moves in an episode ('Episode length') is reached.[3] See Sec. 3.4 for more details on game score and game value.

Classes implementing interface **PlayAgent** and derived from **AgentBase**:

- RandomAgent: an agent acting completely randomly
- HumanPlayer: an agent waiting for user interaction
- MinimaxAgent: a simple tree search (max-tree for 1-player games, min-max-tree for 2-player games)[4]
- MCTSAgent: Monte-Carlo Tree Search agent
- MCAgent: Monte-Carlo agent (no tree)
- TDAgent: general TD(λ) agent (temporal difference, reinforcement learning) with neural network value function (requires a Feature object in constructor, see Sec. 3.5)

Each agent has an **AgentState** member, which is either RAW, INIT or TRAINED.

[1] An *episode* is one specific game playout.

[2] **AgentBase** does not implement all methods of the interface PlayAgent, so it has no `... implements PlayAgent`.

[3] Or, for agents MCTS or MC, when the maximum rollout depth ('Rollout depth') is reached.

[4] Note that Minimax in this simple implementation may not be appropriate for games with random elements, because Minimax follows in each tree step only *one* path of the possible successors that `advance()` may produce.

Some of the agents (RandomAgent, HumanAgent, MinimaxAgent, MCTSAgent, MCAgent) are directly after construction in a TRAINED state, i.e. they are ready-to-use. Minimax, MCTS and MC make their observations on-the-fly, starting from the given state. Some other classes (TDAgent, ...) require training, they are after construction in state INIT.

Classes derived from PlayAgent should implement the `Serializable` interface. This is needed for loading and saving agents. Agent members which should be *not* included in the serialization process have to be flagged with keyword `transient`. Agent members which are user-defined classes should implement the `Serializable` interface as well.

3.3 Some Remarks on the Game Score

Although the game score (the final result of a game, e.g. „X wins“ or „O wins with that many points“) seems to be a pretty simple and obvious concept, it becomes a bit more confusing if one wants to define the game score consistently for a broader class of states, not just for a terminal state. We use the following conventions:

- `PlayAgent.getScore(StateObservation so)` returns the agent's estimate of the final score for the player **who has to move** in StateObservation `so`.[5] The score for 2-player games is usually +1 if it is expected that the player wins finally, 0 if it is a tie and -1 if he loses. Values in between characterize expectation values in cases where different outcomes are possible or likely.

- If a state is terminal (e. g. „X wins“) then the „player who moves“ has changed a last time (i. e. to player O, although the game is over.). Thus the score will be -1 („O loses“). This seems a bit awkward at first sight, but it is the only way to guarantee in a succession of actions for 2-player games that the current score is always the negative of the next state's score (negamax principle). Fig. 1 shows an example.

- `StateObservation.getGameScore()` returns the sum of rewards for the current state. Most 2-player games will give the reward only in the end (win/tie/loss), so that for those games `getGameScore()` is usually 0 as long as the game state is non-terminal. If the game state is terminal, a negative reward will be returned if the player loses and a positive reward

[5] The estimate of the final score – assuming perfect play from all agents – is what we call the *game value* of a state. See Sec. 3.4 for more details on game value.

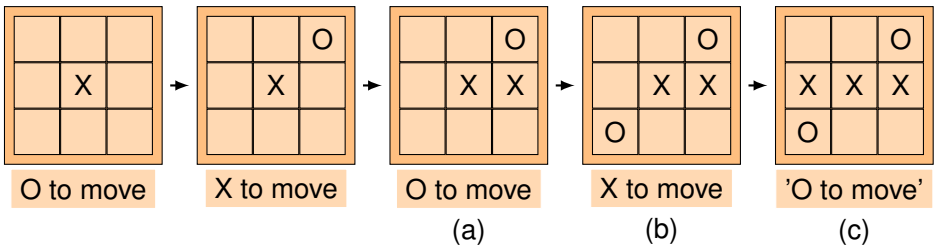

Figure 1: A succession of states in TicTacToe: If O makes in state (a) the losing move leading to (b), then (b) is a clear win for X, so terminal state (c) should be a clear loss for O to be consistent. The game values for (b) and (c) are $+1$ and -1, resp.

if the player wins. The player is always the player who has to move. For other games there might be also rewards during the game.

Example: A 2-player game like TicTacToe is terminal when X makes a winning move. On this terminal state O would have to move next (if it were not terminal). So the game score for this terminal state is a negative reward for player O. It turns out that TicTacToe is always terminated with either a negative reward or a tie.

- `StateObservation.getGameWinner()` may only be called if the game is over for the current state (otherwise an assertion fires). It returns an enum `Types.WINNER` which may be one out of {PLAYER_WINS, TIE, PLAYER_LOSES}. The player is always the player who has to move. The method `Types.WINNER.toInt()` converts these enums to integers which correspond to $\{+1, 0, -1\}$, resp.

StateObservation defines two methods

```
public double getMinGameScore();
public double getMaxGameScore();
```

These methods should return the minimum and maximum game score which can be achieved in a specific game. This is needed since some PlayAgent (e.g. TDAgent) make predictions of the estimated game score with the help of a neural network. Since a neural network has often a sigmoid output function which can emit only values in a certain range (e.g. [0,1]), it is necessary to map the game scores to that range as well. This can only be done if the minimum

and maximum game score is given.[6]

3.4 Difference between Game Score and Game Value

There is a subtle distinction between game score and game value. The **game score** is the score of a game according to the game laws. For example, TicTacToe has the score 0 for all intermediate states, while a terminal state has either +1/0/-1 as game score for win/draw/loss of the player to move. In 2048, the game score is the cumulative sum of all tile merges. Each player usually wants to maximize the expectation value of 'his' score at the end of the game.

But the score in an intermediate game state is not a good indicator of the *potential* of that state. Two states in 2048 might have the same score, but the **game value** of these states can be different. While the first state might be close to the terminal state, the second one might have a higher mobility and thus 'last' longer and receive a higher final score. The precise game value of a state is often not known / not computable, but it is of course desirable to estimate it. An estimate can be based on a simple heuristic like the weighted piece count in chess.

There are (besides PlayAgent's `getGameScore()`) two options to deliver a game value:

1. Interface StateObservation delivers with `getGameValue()` a game-specific (and hard-coded) version of a game value heuristic. If such a heuristic is not known, implementing classes might simply return `getGameScore()`. If a good heuristic is known, this option is simple to implement. It is of course a bit against the idea of general game playing, since knowledge about the game tactics is in one way or the other implicitly coded in such a heuristic.

2. Interface PlayAgent delivers with `estimateGameValue(sob)` a more flexible approach: Such a function can be made trainable / adjustable from previous experiences that the agent has made. For example, a class implementing PlayAgent might learn the game value function from self-play (via trainable weights or via a neural net). The weights have of course to operate on something, therefore a set of features extractable from StateObservation is necessary. [7] These features, normally represented by an object implementing Feature, can be something like number and kind

[6] If a precise maximum game score for a certain game is not known, a reasonable 'big' estimate is usually also sufficient.

[7] The raw state could be used as feature in principle, but it will be in most cases too difficult to establish a mapping from raw features to game value.

of pieces, number of empty cells and so on. See Sec. 3.5 for more information about interface Feature.

It is dependent on the class implementing PlayAgent what

```
estimateGameValue(sob)
```

actually returns. If it is too complicated to train a value function (or if it is simply not needed, because for a game like TicTacToe the simple game score is good enough), then `estimateGameValue(sob)` may simply return `sob.getGameValue()` or `sob.getGameScore()`.

A potential use of `estimateGameValue(sob)` is to compute in MCTS the final value of a random rollout in cases where the rollout did not reach a terminal game state (since the episode lasts longer than the 'Rollout depth' as it is for example in 2048 often the case).

If we integrate a trainable game value estimation into a class implementing PlayAgent, then agents that formerly did not need training (Minimax, MC, MCTS, ...) will require training. They should be after construction in AgentState INIT. How the training is actually done depends fully on the implementing agent.

Is there a need to distinguish between an PlayAgent's `pa.getScore(sob)` and `pa.estimateGameValue(sob)`? – Yes, it is! For a PlayAgent that uses `estimateGameValue(sob)` inside `getScore(sob)` (as it may be the case for Minimax, MCTS and MC), it is necessary to override its method

```
estimateGameValue(sob)
```

in such a way that it does not make a call to `getScore(sob)`. Otherwise an infinite loop would result.

3.5 Interface Feature

Some classes implementing PlayAgent need a game-specific feature vector. As an example, consider TDAgent, the general TD(λ) agent (temporal difference, reinforcement learning) with neural network value function. To make the neural network predict the value of a certain game state, the network needs some feature input (e.g. specific board patterns which form threats or opportunities, number of them, number of pieces and so on). These features are usually game-specific. We assume here that every feature can be expressed as double value (neural networks can only digest real numbers as input), so that the whole feature vector can be expressed as `double[]`.

To create an **Feature** object within the general Arena-code, the *factory method pattern* is used: Arena defines an abstract method

```
public Feature makeFeatureClass(int featmode);
```

The argument `featmode` allows to construct different flavors of Feature objects and to test and evaluate them.

In all cases where Arena or ArenaTrain needs a Feature object, it will call this method `makeFeatureClass(int)`. This will take place whenever a `TDAgent` object is constructed, because the `TDAgent` constructor needs a Feature object as parameter.

Interface Feature has the method

```
public double[] prepareFeatVector(StateObservation so);
```

which gets a game state and returns a double vector of features. This vector may serve as an input for a neural network or other purposes.

Implementing classes: FeatureTTT, Feature2048, ...

3.6 Interface GameBoard

Interface **GameBoard** has the game board GUI (usually in a separate JFrame). It provides functionality for:

- Maintaining its own StateObservation object `m_so`. This object is after construction in a default start state (e. g. empty board). The same state can be reached via `clearBoard()` or `getDefaultStartState()` as well. The associated GUI will show the default start state.
- Showing or updating the current game state (StateObservation) in the GUI and enabling / disabling the GUI elements (`updateBoard(...)`).
- Human interaction with the board: see Sec. 3.7.
- Returning its current StateObservation object (`getStateObs()`).
- `chooseStartState01()`: This method returns randomly one out of a set of different start states. This is useful when training an agent so that not always the same game episode is played but some variation (exploration) occurs.

  Example for TicTacToe: The implementation in GameBoardTTT returns with probability 0.5 the default start state (empty board) and with probability 0.5 one out of the possible next actions (an 'X' in any of the nine board positions).

Implementing classes: GameBoardTTT, GameBoard2048, ...

3.7 Human interaction with the board and with Arena

During game play: How is the integration between user actions (human moves) and AI agent actions implemented?

If GameBoard request an action from Arena, then its method `isActionReq()` returns `true`. This causes the selected AI to perform a move. If on the other hand a human interaction is requested, Arena issues a `setActionReq(false)` and this causes `isActionReq()` to return `false` as well. GameBoard then waits for GUI events until a user (human) action is recorded. GameBoard is responsible for checking whether the human action is legal (`isLegalAction()`).[8] If so, then GameBoard issues an `advance()`. Method `advance()` opens the possibility for invoking random elements from the game environment (e. g. adding a new tile in 2048), if necessary.

When all this has happened, GameBoard sets its internal state such that `isActionReq()` returns `true` again. Thus it asks Arena for the next action and the cycle continues. Finally, Arena detects an `isGameOver()`-condition and finishes the game play.

3.8 Abstract Class Evaluator

Class **Evaluator** evaluates the performance of a PlayAgent.

In the constructor

```
public Evaluator(PlayAgent e_PlayAgent, int stopEval,
                 int mode, int verbose);
```

the argument `mode` allows derived classes to create different types of evaluators. These may test different abilities of PlayAgent. The argument `stopEval` sets the number of consecutive evaluations that the abstract method

```
abstract protected boolean eval_Agent();
```

has to return with `true` until the evaluator is said to reach its goal (method `goalReached()`). This is used in XArenaFunc's method `train()` as a possible condition to stop training prematurely.

Method `evalAgent()` needs to be overridden by classes derived from Evaluator.

Concrete objects of class Evaluator are usually constructed by the factory method

[8] see method `HGameMove(x,y)` in GameBoardTTT for an example.

```
abstract public Evaluator makeEvaluator(PlayAgent e_PlayAgent,
                int stopEval, int mode, int verbose);
```

in Arena or ArenaTrain.

3.9 Abstract Class Arena

Class **Arena** is an abstract class for loading agents and playing games. Why is it an abstract class? – **Arena** has to create an object implementing interface GameBoard, and this object will be game-specific, e. g. a GameBoardTTT object. To create such an object within the general Arena-code, the *factory method pattern* is used: Arena defines the abstract methods

```
abstract public GameBoard makeGameBoard();
abstract public Evaluator makeEvaluator(...);
```

The first method is a factory method for GameBoard objects. The second method is a factory method for Evaluator objects. Both will be implemented by classes derived from Arena. That is, a derived class ArenaTTT can be very thin, it just implements the methods `makeGameBoard()` and `makeEvaluator()` and lets them return (in the example of TicTacToe) GameBoardTTT and EvaluatorTTT objects, resp.

Class Arena has in addition the factory method

```
public Feature makeFeatureClass(int);
```

If it is not overridden by derived classes, it will throw a `RuntimeException` (no game-tailored Feature object available). If a class derived from Arena wants to use a trainable agent requiring Feature (e. g. `TDAgent`) then it has to override `makeFeatureClass`.

Class Arena has the following functionality:

- choice of agents for each player (load)
- playing games (AI agents & humans)
- inspecting the move choices of an agent
- (TODO) logging of played games (option for later replay or analysis)
- (TODO) undo/redo possibilities
- (TODO) game balancing
- (TODO) game leagues, round-robin tournaments, ...

Derived abstract class: ArenaTrain. Derived non-abstract classes: ArenaTTT, Arena2048, ...

3.10 Abstract Class ArenaTrain

Class **ArenaTrain** is an abstract class derived from Arena which has additional functionality:

- specifying all parameters for an agent
- training an agent (one or multiple times)
- evaluating agents, competitions (one or multiple times)
- saving agents
- (TODO) replay memory for better training

The helper classes XArenaFuncs, XArenaButtons, XArenaMenu, XArenaTabs contain functionality needed for Arena and ArenaTrain.

Derived non-abstract classes: ArenaTrainTTT, ArenaTrain2048, ...

4 Use Cases and FAQs

4.1 I have implemented game XYZ and want to use AI agents from GBG – what do I have to do?

As a game developer you have to implement the following four interfaces for your game:

- `StateObserverXYZ implements StateObservation`
- `GameBoardXYZ implements GameBoard`
- `EvaluatorXYZ extends Evaluator`
- `FeatureXYZ extends Feature` (only needed, i. e. if the game wants to use trainable agents like `TDAgent`).

Once this is done, you only need to write a very 'thin' class ArenaTrainXYZ with suitable constructors, which overwrites the abstract methods of class ArenaTrain with the factory pattern methods

```
public GameBoard makeGameBoard() {
   gb = new GameBoardXYZ(this);
   return gb;
}
```

```
public Evaluator makeEvaluator(PlayAgent pa, GameBoard gb,
                  int stopEval, int mode, int verbose) {
   return new EvaluatorXYZ(pa,gb,stopEval,mode,verbose);
}
```

If needed, you should overwrite the method

```
public Feature makeFeaturClass(int featmode) {
   return new FeatureXYZ(featmode);
}
```

as well.

Finally you need a class with `main()` to launch ArenaTrain. You may copy and adapt the example in `LaunchTrainTTT`.

Then you can use for your game all the functionality laid down in ArenaTrain and all the wisdom of the AI agents implementing PlayAgent. Cool, isn't it?

4.2 How to train an agent and save it

1. Create an ArenaTrain object
2. Select an agent and set its parameters
3. Set training-specific parameters:
   - `maxTrainNum`: 'Training games' = number of training episodes,
   - `numEval`: after how many episodes an intermediate evaluation is done,
   - `epiLength`: 'Episode length' = maximum allowed number of moves in a training episode. If it is reached, the game is stopped and `PlayAgent.estimateGameValue()` is returned (either up-to-now-reward or estimate of current + future rewards). If the game terminates earlier, the final game score is returned.
4. Train the agent & visualize intermediate evaluations.
5. Optional: Inspect the agent (how it responds to certain board situations).
6. Save the agent

4.3 Which AI's are currently implemented for GBG?

The following AI's (agents) are currently implementing interface PlayAgent:

- Class TDAgent (Temporal difference reinforcement learning)
- Class MCTS (Monte Carlo Tree Search)
- Class MC (pure Monte Carlo search)
- Class MinimaxAgent (Minimax tree search of prescribed depth)
- Class RandomAgent

4.4 How to write a new TD agent for a specific game?

Suppose you have implemented a new game XYZ and want to write a TD agent (temporal difference agent) which learns this game. What do you have to do? – Luckily, you can re-use most of the functionality laid down in class **TDAgent** (see Sec. 3.2).

1. Write a new Feature class

   ```
   public class FeatureXYZ implements Feature, Serializable
   ```

   This is the only point where some code needs to be written: Think about what features are useful for your game. In the simplest case this might be the raw board positions, but these features may characterize the win- or loose-probability for a state only rather indirectly. Other patterns may characterize the value (or the danger) of a state more directly. For example, in the game TicTacToe any two-in-a-row opponent pieces accompanied by a third empty position pose an immanent threat. A typical feature may be the count of those threats. N-tuple sets (Lucas [2008], Bagheri et al. [2015], Thill [2015]) are another way of generating a large number of features in a generic way.

2. Add to ArenaXYZ and ArenaTrainXYZ the overriding method

   ```
   public Feature makeFeatureClass(int featmode) {
       return new FeatureXYZ(featmode);
   }
   ```

In any case, **TDAgent** will generate by reinforcement learning a mapping from feature vectors to values (final score estimates) for all relevant game states.

The class ArenaTrainTTT (together with FeatureTTT) may be inspected to view a specific example for the game TicTacToe.

5 Open Issues

The current GBG class framework is still in its test phase. The design of the classes and interfaces may need further reshaping when more games or agents are added to the framework. There are a number of items not fully tested or not yet addressed:

- The GUI for Arena and ArenaTrain is just a quick hack adapted from earlier programs and may need further refinement.
- The above-mentioned elements for Arena and ArenaTrain that are planned but not yet implemented:
  - (TODO) Add Arena and ArenaTrain launchers which allow to select between the different implemented games and then launch the appropriate derived Arena and ArenaTrain class.
  - (TODO) logging of played games (option for later human replay or analysis), logging of competition games
  - (TODO) undo/redo possibilities
  - (TODO) a slider during agent-agent game play to control the playing velocity. Optional game visualization during competitions as well.
  - (TODO) game balancing
  - (TODO) game leagues, round-robin tournaments, ...
  - (TODO) option to enable/disable value function display during game play
  - (TODO) client-server architecture for game play via applet on a game page. Option for a 'hall of fame'. An example for the game Hexi is found under http://www.dbai.tuwien.ac.at/proj/ramsey.
  - (TODO) Implement the game Sim (= Hexi) in the Arena and ArenaTrain framework. A Java code example of the Sim board GUI may be found under http://www.dbai.tuwien.ac.at/proj/ramsey. Generalize the number of nodes (not only 6). Later, one may create a 3-player variant of Sim and test the framework on this.

  - (TODO) Replay memory for better training: This is the idea used by DeepMind in learning Atari video games. Played episodes are stored in a replay memory pool and used repeatedly for training.

- The extension to n-player games ($n > 2$) is not fully functional yet. An example to fully implement and test n-player games can be the 3-player variant of the game Sim. The cases $n = 1$ and $n = 2$, which are fully functional, need also to be tested on a variety of 1- and 2-player games.
- The n-tuple agents developed for C4 (Connect Four) and TTT need to be ported to GBG.
- Allow only trained agents to be saved.
- Clarify: Is the parameter data flow safe, if we issue a 'play' or 'compete' for 2 agents of same type but with different parameters?

A Appendix

A.1 Interface StateObservation

```
/**
 * Class StateObservation observes the current state of the game,
 * it has utility functions for
 * <ul>
 * <li> returning the available actions (getAvailableActions()),
 * <li> advancing the state of the game with a specific action (advance()),
 * <li> copying the current state
 * <li> signaling end, score and winner of the game
 * </ul>

public void storeBestActionInfo(ACTIONS actBest, double[] vtable);
public int getNumPlayers(); // n
public int getPlayer();     // (0,1,...,n-1)
public int getPlayerPM();   // (+1,-1) for a 2-player game
}
```

A.2 Interface GameBoard

```
/**
 * Each class implementing interface GameBoard has the board game GUI.
 *
 * It has an internal object derived from StateObservateion which
 * represents the current game state. It can be retrieved (getStateObs()),
 * reset and retrieved (getDefaultStartState()) or a random start
 * state can be chosen (@link #chooseStartState01()).
 * @author Wolfgang Konen, TH Köln, Nov'16
 */
public interface GameBoard {

public void clearBoard(boolean boardClear, boolean vClear);
public void updateBoard(StateObservation so, boolean showStoredV,
            boolean enableOccupiedCells);
public void showGameBoard(ArenaTrain ticGame);
public boolean isActionReq(); // action requested from Arena?
public void setActionReq(boolean actionReq);
public void enableInteraction(boolean enable);
public StateObservation getStateObs();
public StateObservation getDefaultStartState(); // empty-board state
public StateObservation chooseStartState01();
}
```

A.3 Interface PlayAgent

```
/**
 * The abstract interface for the game playing agents.
 *
 * @author Wolfgang Konen, TH Köln, Nov'16
 */
public interface PlayAgent {
public enum AgentState {RAW, INIT, TRAINED};

public Types.ACTIONS getNextAction(StateObservation sob, boolean random,
                    double[] vtable, boolean silent);
public double getScore(StateObservation sob);
public double estimateGameValue(StateObservation sob);
public boolean wasRandomAction(); // was last getNextAction random?
public boolean trainAgent(StateObservation so); // for one episode
public boolean trainAgent(StateObservation so,
               int epiLength);        // with episode length limit
public String printTrainStatus();
public String stringDescr();
public String getName();
public void setName(String name);
public AgentState getAgentState();
public void setAgentState(AgentState aState);
public int getMaxGameNum();
public void setMaxGameNum(int num);
public int getGameNum();
public void setGameNum(int num);
}
```

A.4 Interface Feature

```
/**
 * Interface Feature translates game states into feature vectors.
 *
```

```
 * Method prepareFeatVector(so) returns the feature vector
 * for state so. Child classes have usually constructors accepting a
 * single argument 'featmode'. The argument 'featmode' allows to
 * construct different flavors of Feature objects.
 * The acceptable values for 'featmode' in a certain child class
 * are retrieved with getAvailFeatmode().
 */
public interface Feature {
public double[] prepareFeatVector(StateObservation so);
public String stringRepr(double[] featVec);
public int getFeatmode();
public int[] getAvailFeatmode();
}
```

A.5 Abstract class Evaluator

```
/**
 * Evaluates the performance of a PlayAgent in a game.
 */
abstract public class Evaluator {
protected PlayAgent m_PlayAgent;
protected int verbose=1;
public Evaluator(PlayAgent e_PlayAgent, int stopEval);
public Evaluator(PlayAgent e_PlayAgent, int stopEval, int verbose);
public boolean eval();
public boolean goalReached(int gameNum);
public boolean setState(boolean stateE);
public boolean getState();
public String getMsg();
public String getMsg(int gameNum);
abstract protected boolean eval_Agent();
abstract public double getLastResult();
}
```

A.6 Abstract class Arena

```
/**
```

```
 * This class contains the GUI and the task dispatcher for the game.
 * The GUI for buttons and choice boxes is in {@link XArenaButtons}.
 *
 * Run this class from the {@code main} in {@link LaunchArenaTTT})
 * for the TicTacToe game.
 *
 * @author Wolfgang Konen, TH Köln, Nov'16
 */
abstract public class Arena extends JPanel implements Runnable
{
public enum Task {PARAM, TRAIN, MULTTRN, PLAY, INSPECTV
                  , COMPETE, SWAPCMP, MULTCMP, IDLE  };
protected GameBoard gb;
public Task taskState;
public Arena();
public Arena(JFrame);
public void init();
public void run();
public void PlayGame();
public void enableButtons(boolean state);
public void setStatusMessage(String msg);
public StatusBar getStatusBar();
public Feature makeFeatureClass(int featmode);
abstract public String getGameName();
abstract public GameBoard makeGameBoard();
abstract public Evaluator makeEvaluator(PlayAgent pa, GameBoard gb,
                int stopEval, int mode, int verbose);
abstract public void performArenaDerivedTasks();
}
```

A.7 Abstract class ArenaTrain

```
/**
 * This class contains the GUI for the arena with train capabilities.
 * It extends the task dispatcher of Arena with method
 * performArenaDerivedTasks() which contains tasks to trigger functions
 * for agent learning, parameterization, inspection and so on.
 *
```

```
 * @author Wolfgang Konen, TH Köln, Nov'16
 */
abstract public class ArenaTrain extends Arena
{
public ArenaTrain();
public ArenaTrain(JFrame frame);
public void performArenaDerivedTasks();  // extend task dispatcher
protected void InspectGame(); // inspect agent X on game positions
}
```
